- 8 Monads

# What is Functional Programming?

A different approach to programming

# **Functions and values**

rather than

Assignments and addresses

# What is Functional Programming?

A different approach to programming

# **Functions and values**

rather than

# Assignments and addresses

It will make you a better programmer

# Functional vs Imperative Programming: Variables

# Functional (Haskell)

1 × :: Int

 $\begin{vmatrix} 1 & 1 & 1 \\ 2 & 1 & 2 \end{vmatrix}$ 

- Variable x has value 5 forever
- It's ok to replace x by 5 whenever needed

# Functional vs Imperative Programming: Variables

#### Functional (Haskell)

```
|x| :: Int
|x| = 5
```

- Variable x has value 5 forever
- It's ok to replace x by 5 whenever needed

#### Imperative (Java / C)

```
int x = 5;
2 ...
3 x = x+1;
```

- Variable x can change its content over time
- Current value of x needs to be looked up in the store

# Functional vs Imperative Programming: Functions

#### Functional (Haskell)

```
f :: Int -> Int -> Int
f x y = 2*x + y
f 42 16 // always 100
```

Return value of a function **only** depends on its inputs

# Functional vs Imperative Programming: Functions

#### Functional (Haskell)

```
f:: Int -> Int -> Int
f x y = 2*x + y
f 42 16 // always 100
```

Return value of a function **only** depends on its inputs

#### Imperative (Java)

```
boolean flag;
static int f (int x, int y) {
    return flag ? 2*x + y , 2*x - y;
}
int z = f (42, 16); // who knows?
```

Return value depends on non-local variable flag

# Functional vs Imperative Programming: Laziness

#### Haskell

x = expensiveComputation g anotherExpensiveComputation

- The expensive computation will only happen if x is ever used.
- Another expensive computation will only happen if g uses its argument.

# Functional vs Imperative Programming: Laziness

#### Haskell

x = expensiveComputation g anotherExpensiveComputation

- The expensive computation will only happen if x is ever used.
- Another expensive computation will only happen if g uses its argument.

#### Java

int x = expensiveComputation; g (anotherExpensiveComputation)

- Both expensive computations will happen anyway.
- Laziness can be simulated, but it's complex!

# Many features that make programs more concise

- Pattern Matching
- Higher-order functions
- Algebraic datatypes
- Polymorphic types
- Parametric overloading
- Type inference
- Monads & friends (for IO, concurrency, . . . )
- Comprehensions
- Metaprogramming
- Domain specific languages
- . . .

#### Plan

- Introduction
- 2 Types
- Pattern Matching on Lists
- Input and Output
- 6 Algebraic Datatypes
- Type classes
- Search trees and expression trees
- 8 Monads

### **Predefined Types**

Every Haskell value has a type

```
Bool
                 — True :: Bool, False :: Bool
Char
                 — 'x':: Char, '?':: Char, . . .
Double, Float — 3.14 :: Double
Integer
                 — 4711 :: Integer
Int
                 — machine integers (\geq 30 bits signed integer)
()
                 — the unit type, single value () :: ()
                 — function types
a -> b
                 — tuple types
(a, b)
                 — list types
[a]
                 — "xyz":: String, . . .
String
```

#### **Functions**

# Examples.hs dollarRate = 1.3671 -- |convert EUR to USD

- dollarRate defines a constant
- usd is a function

 $_{4}$  usd euros = euros \* dollarRate

- Its type Double -> Double is inferred by the Haskell compiler
- To compute, a function call usd arg is replaced by the right hand side of its definition

```
usd arg 
ightarrow arg * dollarRate 
ightarrow arg * 1.3671 
ightarrow . . .
```

#### Recursive functions

#### Compute x^n without using the built-in operator

```
 \begin{array}{l} 1 \\ -- \text{ compute } x \text{ to } n-\text{th power} \\ power x \text{ n } \mid \text{ n} == 0 = 1 \\ 3 \\ power x \text{ n } \mid \text{ n} > 0 = x * \text{ power } x \text{ (n } -1) \end{array}
```

- defined using guarded equations
- computation chooses the first equation such that the guard is true
  - ightharpoonup power 5 0 ightharpoonup 1
  - ▶ power 5 2  $\rightarrow$  5 \* power 5 1  $\rightarrow$  5 \* (5 \* power 5 0)  $\rightarrow$  5 \* (5 \* 1)

# **Tuples**

```
-- example tuples
examplePair :: (Double, Bool) -- Double x Bool
examplePair = (3.14, False)

exampleTriple :: (Bool, Int, String) -- Bool x Int x String
exampleTriple = (False, 42, "Answer")

exampleFunction :: (Bool, Int, String) -> Bool
exampleFunction (b, i, s) = not b && length s < i
```

#### Summary

- Syntax for tuple type like syntax for tuple values
- Tuples are immutable: in fact, all values are!
   Once a value is defined it cannot change!

# Typing for Tuples

#### Typing Rule

$$\frac{\text{TUPLE}}{\underbrace{e_1 :: t_1 \qquad e_2 :: t_2 \qquad \ldots \qquad e_n :: t_n}}{\left(e_1, \ldots, e_n\right) :: \left(t_1, \ldots, t_n\right)}$$

lf

- $e_1, \ldots, e_n$  are Haskell expressions
- $t_1, \ldots, t_n$  are their respective types
- ullet Then the tuple expression  $(e_1,\ldots,e_n)$  has the tuple type  $(t_1,\ldots,t_n)$ .

#### Lists

- The "duct tape" of functional programming
- Collections of things of the same type
- For any type a, [a] is the type of lists with elements of type a
  e.g. [Bool] is the type of lists of Bool
- Syntax for list type like syntax for list values
- Lists are **immutable**: once a list value is defined it cannot change!

# Constructing lists

#### The values of type [a] are . . .

- either [], the empty list
- or x:xs where x has type a and xs has type [a]":" is pronounced "cons"
- [] and (:) are the list constructors

# Constructing lists

#### The values of type [a] are . . .

- either [], the empty list
- or x:xs where x has type a and xs has type [a]":" is pronounced "cons"
- [] and (:) are the list constructors

#### Typing Rules for Lists

$$\begin{array}{c} \text{Nil} & \text{Cons} \\ \left[\right] :: \left[t\right] & \frac{e_1 :: t \quad e_2 :: \left[t\right]}{\left(e_1 : e_2\right) :: \left[t\right]} \end{array}$$

- The empty list can serve as a list of any type t
- If there is some t such that  $e_1$  has type t and  $e_2$  has type [t], then  $(e_1 : e_2)$  has type [t].

#### List shorthands

#### Equivalent ways of writing a list

```
1:(2:(3:[])) — standard, fully parenthesized
```

1:2:3:[] — (:) associates to the right

[1,2,3] — bracketed notation

# Typing Lists

# Quiz Time Which of the following expressions have type [Bool]? [ ] True : [ ] True : False False : (False : [ ]) (False : False) : [ ] (False : []) : [ ] (True : (False : (True : []))) : (False:[]):[ ]

#### Plan

- Introduction
- 2 Types
- Pattern Matching on Lists
- 4 Input and Output
- 6 Algebraic Datatypes

- Search trees and expression trees
- 8 Monads

#### Functions on lists

# Definition by pattern matching

```
 \begin{array}{l} -- \text{ double every element of a list of integers: double } [3,6,12] == [6,12,24] \\ \text{doubles :: [Integer] } -> [Integer] \\ \text{doubles } [] = [] \\ \text{doubles } (x:xs) = (2*x) : \text{doubles } xs \\ \end{array}
```

#### Functions on lists

#### Definition by pattern matching

```
-- double every element of a list of integers: double [3,6,12] == [6,12,24] doubles :: [Integer] -> [Integer] doubles [] = [] doubles (x:xs) = (2 * x) : doubles xs
```

#### Argument value is checked against patterns

- patterns contain constructors ([] and :) and variables
- patterns are checked in sequence; matching equation is chosen
- constructors are checked against argument value
- variables are bound to the values in corresponding position in the argument

#### Functions on lists

#### Definition by pattern matching

```
-- double every element of a list of integers: double [3,6,12] == [6,12,24] doubles :: [Integer] -> [Integer] doubles [] = [] doubles (x:xs) = (2 * x) : doubles xs
```

# Argument value is checked against patterns

- patterns contain constructors ([] and :) and variables
- patterns are checked in sequence; matching equation is chosen
- constructors are checked against argument value
- variables are bound to the values in corresponding position in the argument

#### Example evaluation

```
doubles (3 : 6 : 12 : []) \rightarrow (2 * 3) : doubles (6 : 12 : []) \rightarrow 6 : (2 * 6) : doubles (12 : []) \rightarrow . . .
```

#### Definition

A higher-order function takes a function argument or returns it as a result.

#### Definition

A higher-order function takes a function argument or returns it as a result.

```
twice :: (a -> a) -> (a -> a)
twice f x = f (f x)
```

- twice takes a function f and an argument and applies f two times to the argument.
- (+1) is the function that adds one to its argument
- What is twice (+1)?

#### Definition

A higher-order function takes a function argument or returns it as a result.

```
twice :: (a -> a) -> (a -> a)
twice f x = f (f x)
```

- twice takes a function f and an argument and applies f two times to the argument.
- (+1) is the function that adds one to its argument
- What is twice (+1)?
- That's the function that adds two to its argument!

#### Definition

A higher-order function takes a function argument or returns it as a result.

```
twice :: (a -> a) -> (a -> a)
twice f x = f (f x)
```

- twice takes a function f and an argument and applies f two times to the argument.
- (+1) is the function that adds one to its argument
- What is twice (+1)?
- That's the function that adds two to its argument!
- But what about twice twice (+1)?

#### Definition

A higher-order function takes a function argument or returns it as a result.

```
twice :: (a -> a) -> (a -> a)
twice f x = f (f x)
```

- twice takes a function f and an argument and applies f two times to the argument.
- (+1) is the function that adds one to its argument
- What is twice (+1)?
- That's the function that adds two to its argument!
- But what about twice twice (+1)?
- Adds four!

# map: Apply Function to Every Element of a List

#### Definition

```
 \begin{array}{l} -- \text{ map } f \left[ x1, \, x2, \, ..., \, xn \right] = \left[ f \, x1, \, f \, x2, \, ..., \, fn \right] \\ \text{map } :: \left( a \, -> \, b \right) \, -> \left[ a \right] \, -> \left[ b \right] \\ \text{map } f \left[ \right] = \left[ \right] \\ \text{map } f \left( x:xs \right) = f \, x : \, map \, f \, xs \end{array}
```

(map is in the standard Prelude - no need to define it)

# map: Apply Function to Every Element of a List

#### Definition

```
\begin{array}{ll}
    -- & \text{map f } [x1, x2, ..., xn] = [f x1, f x2, ..., fn] \\
    \text{map :: } (a -> b) -> [a] -> [b] \\
    \text{map f } [] = [] \\
    \text{map f } (x:xs) = f x : map f xs
\end{array}
```

(map is in the standard Prelude - no need to define it)

#### Defining doubles using map

```
doubles xs = map (*2) xs
```

#### foldr: Reduce a List

#### Abstracting over value and combining function

```
foldr :: (a -> b -> b) -> b -> [a] -> b
foldr op e [] = e
foldr op e (x:xs) = x 'op' foldr' op e xs
```

#### where

- e :: b is a value replacing the empty list
- op :: a -> b -> b is a combining function for list element and recursive call on the rest

#### foldr: Reduce a List

#### Abstracting over value and combining function

```
foldr :: (a -> b -> b) -> b -> [a] -> b
foldr op e [] = e
foldr op e (x:xs) = x 'op' foldr' op e xs
```

#### where

- e :: b is a value replacing the empty list
- op :: a -> b -> b is a combining function for list element and recursive call on the rest

# Example: many functions become one-liners with foldr

```
\begin{bmatrix} sum \ xs = foldr \ (+) \ 0 \ xs \end{bmatrix} product xs = foldr \ (*) \ 1 \ xs
```

#### foldr: Reduce a List

#### Abstracting over value and combining function

```
foldr :: (a -> b -> b) -> b -> [a] -> b
foldr op e [] = e
foldr op e (x:xs) = x 'op' foldr' op e xs
```

#### where

- e :: b is a value replacing the empty list
- op :: a -> b -> b is a combining function for list element and recursive call on the rest

# Example: many functions become one-liners with foldr

```
\begin{vmatrix} \text{sum xs} = \text{foldr}(+) & \text{0 xs} \\ \text{product xs} = \text{foldr}(*) & \text{1 xs} \end{vmatrix}
```

#### Also known as reduce

map + reduce = MapReduce

# Referential transparency and substitutivity

### Recall the beginning

- Every variable and expression has just one value referential transparency
- Every variable can be replaced by its definition substitutivity

# Referential transparency and substitutivity

## Recall the beginning

- Every variable and expression has just one value referential transparency
- Every variable can be replaced by its definition substitutivity

# Referential transparency enables reasoning

## Bad example

Suppose we had an operation that reads a number from the terminal

input :: () -> Integer

## Bad example

Suppose we had an operation that reads a number from the terminal

```
input :: () -> Integer
```

Consider

```
\begin{vmatrix}
let x = input () & in \\
2 & x + x
\end{vmatrix}
```

## Bad example

Suppose we had an operation that reads a number from the terminal

```
input :: () -> Integer
```

Consider

```
\begin{vmatrix} 1 & \text{let } x = \text{input () in} \\ 2 & x + x \end{vmatrix}
```

Expectation: read one input and use it twice

## Bad example

Suppose we had an operation that reads a number from the terminal

```
input :: () -> Integer
```

Consider

```
\begin{array}{c|c}
1 & \text{let } x = \text{input () in} \\
2 & x + x
\end{array}
```

- Expectation: read one input and use it twice
- By substitutivity, this expression must behave like

```
input () + input ()
```

which reads two inputs!

## Bad example

Suppose we had an operation that reads a number from the terminal

```
input :: () -> Integer
```

Consider

- Expectation: read one input and use it twice
- By substitutivity, this expression must behave like

```
input () + input ()
```

which reads two inputs!

VERY WRONG!!!

### The dilemma

Haskell is a pure language, but I/O is a side effect

### The dilemma

Haskell is a pure language, but I/O is a side effect

A contradiction?

### The dilemma

Haskell is a pure language, but I/O is a side effect

#### A contradiction?

#### No!

- Instead of performing IO operations directly, there is an abstract type of IO instructions, which get executed lazily by the operating system
- Some instructions (e.g., read from a file) return values, so the abstract IO type is parameterized over their type
- Keep in mind: instructions are just values like any other

# Haskell I/O

#### The main function

Top-level result of a program is an IO "instruction".

```
main :: IO ()
main = putStrLn "Hello World!"
```

- an instruction describes the effect of the program
- effect = IO action, imperative state change, ...
- Here: print a string on the terminal

### Kinds of instructions

### Primitive instructions

```
_2 putChar :: Char -> IO ()
getChar :: IO Char
|\Psi| writeFile :: FileName -> String -> IO ()
```

#### and many more

### Kinds of instructions

### Primitive instructions

```
-- predefined
putChar :: Char -> IO ()
getChar :: IO Char
writeFile :: FileName -> String -> IO ()
readFile :: FileName -> IO String
```

#### and many more

### No op instruction

```
_{1} return :: a -> 10 a
```

The IO instruction return 42 performs no IO, but yields the value 42.

# Combining two instructions

## The bind operator >>=

Intuition: next instruction may depend on the output of the previous one

The instruction m >>= f

- first executes m :: IO a
- gets its result x :: a
- applies f :: a -> IO b to the result
- to obtain an instruction f x :: IO b that returns a b
- and executes this instruction to return a b

# Combining two instructions

### The bind operator >>=

Intuition: next instruction may depend on the output of the previous one

The instruction m >>= f

- first executes m :: IO a
- gets its result x :: a
- applies f :: a -> IO b to the result
- ullet to obtain an instruction f x :: IO b that returns a b
- and executes this instruction to return a b

### Example

```
readFiles f1 f2 = | readFiles f1 f2 = | readFiles f1 >>= | readFiles f2 | readFiles f1 f2 | readFiles f
```

## Instructions vs functions

#### **Functions**

behave the same each time they called

### Instructions vs functions

#### **Functions**

behave the same each time they called

#### Instructions

may be interpreted differently each time they are executed, depending on context

# Underlying concept: Monad

#### What's a monad?

- abstract type for instructions that produce values
- built-in operators combination >>= and no-op return
- abstracts over different interpretations (computations)

# Underlying concept: Monad

#### What's a monad?

- abstract type for instructions that produce values
- built-in operators combination >>= and no-op return
- abstracts over different interpretations (computations)

### IO is a special case of a monad

- one very useful application for monads
- built into Haskell
- but there's more to the concept!

## Plan

- Introduction
- 2 Types
- Pattern Matching on Lists
- 4 Input and Output
- 6 Algebraic Datatypes
- Type classes
- Search trees and expression trees
- 8 Monads

# Algebraic Datatypes

- Signature facility for defining datatypes in functional languages
- Describe a new datatype by declaring its constructor functions and giving the type of their arguments
- Constructor functions do not evaluate their arguments (like the list constructors 
   ☐ and :)
- Constructors can be used for pattern matching on the left side of function definitions

# Example scenario

## Model a card game

- represent the game items!
- define game logic on the representations!

# Data model for card games

## Description

- A card has a Suit and a Rank
- A card beats another card if it has the same suit, but higher rank

# Data model for card games

## Description

- A card has a Suit and a Rank
- A card beats another card if it has the same suit, but higher rank

### A card has a Suit

data Suit = Spades | Hearts | Diamonds | Clubs

# Data model for card games

### Description

- A card has a Suit and a Rank
- A card beats another card if it has the same suit, but higher rank

### A card has a Suit

```
| data Suit = Spades | Hearts | Diamonds | Clubs |
```

### Explanation

- new type consisting of four values
- Suit: the name of the new type
- Spades, Hearts, ...: the names of its **constructors**.
- Type and constructor names must be capitalized

### More data

#### A card has a suit and a rank:

```
_{1} \bigg| \, \mathsf{data} \,\, \mathsf{Rank} = \mathsf{Numeric} \,\, \mathsf{Integer} \,\, | \,\, \mathsf{Jack} \,\, | \,\, \mathsf{Queen} \,\, | \,\, \mathsf{King} \,\, | \,\, \mathsf{Ace}
```

The constructor Numeric is different: it takes an argument.

```
1 Main> :t Numeric
```

2 Numeric :: Integer -> Rank

# Defining a function on Rank

#### Ordering ranks by pattern matching

```
1 -- rankBeats r1 r2 returns True, if r1 beats r2
_{2} rankBeats :: Rank -> Rank -> Bool
_{3} rankBeats Ace = False
4 rankBeats Ace = True
5 rankBeats _ King = False
6 rankBeats King _ = True
7 rankBeats _ Queen = False
|s| rankBeats Queen _{-} = True
9 rankBeats Jack = False
10 rankBeats Jack _ = True
| rankBeats (Numeric n1) (Numeric n2) = n1 > n2
|--| pattern match on constructor
13 -- yields its argument
```

## Example

```
rankBeats Queen Jack == True rankBeats Queen King == False
```

# Datatypes can be recursive

### Binary Trees

A binary tree is either

- empty or
- it is a node with a data element and two subtrees.

```
|a| data BTree a = Leaf | Node (BTree a) a (BTree a)
```

- Parameterised over the type a of elements
- Recursive datatype definition
- Two arguments of Node refer to the currently defined type BTree a
- Leaf is the base case

## Plan

- Introduction

- 8 Monads

# Haskell integrates overloading with polymorphism

### Restricted polymorphism

- Some functions work on parametric types, but are restricted to specific instances
- Types contain type variables and constraints

# Haskell integrates overloading with polymorphism

### Restricted polymorphism

- Some functions work on parametric types, but are restricted to specific instances
- Types contain type variables and constraints

### Examples

```
-- elem x xs : is x an element of list xs?

-- type a must support equality

elem :: Eq a => a -> [a] -> Bool

-- insert x xs : insert x into sorted list xs

-- type a must support comparison
insert :: Ord a => a -> [a] -> [a]

-- square x : compute the square of x

-- type a supports numeric operations

square :: Num a => a -> a
```

# Type classes

- Each constraint mentions a **type class** like Eq. Ord, Num, . . .
- A type class is a set of types that support the same operations
   e.g. Eq requires == and /=
- Type classes form a hierarchy
   e.g. Ord a => Eq a
- Many classes are predefined, but you can roll your own

### Classes and Instances

 A class declaration only specifies a signature (i.e., the class members and their types)

```
class Num a where
(+), (*), (-) :: a -> a -> a
negate, abs, signum :: a -> a
fromInteger :: Integer -> a
```

 A separate instance declaration specifies that a type belongs to a class by giving definitions for all class members

```
instance Num Int where ...
instance Num Integer where ...
instance Num Double where ...
instance Num Float where ...
```

# Example: Equality

## The type class Eq

```
class Eq a where
```

(==), (/=) :: a -> a -> Bool

x /= y = not (x == y) -- default definition

An instance must only provide (==).

# Example: Equality

## The type class Eq

```
class Eq a where
```

(==), (/=) :: a -> a -> Bool

x /= y = not (x == y) -- default definition

An instance must only provide (==).

### Question

Does equality make sense at every type?

When are two pairs equal?

### When are two pairs equal?

### Solution

```
instance (Eq a, Eq b) => Eq (a, b) where
(a1, b1) == (a2, b2) = a1 == a2 && b1 == b2
```

## When are two pairs equal?

#### Solution

```
instance (Eq a, Eq b) => Eq (a, b) where
(a1, b1) == (a2, b2) = a1 == a2 && b1 == b2
```

Is this definition recursive?

### When are two pairs equal?

#### Solution

```
instance (Eq a, Eq b) => Eq (a, b) where
```

$$(a1, b1) == (a2, b2) = a1 == a2 \&\& b1 == b2$$

Is this definition recursive?

#### NO!

## Defining Eq for Suit

#### Manual definition

```
data Suit = Spades | Hearts | Diamonds | Clubs

instance Eq Suit where
Spades == Spades = True
Hearts == Hearts = True
Diamonds == Diamonds = True
Clubs == Clubs = True

== _ = False // any other combination
```

## Defining Eq for Suit

#### Manual definition

```
data Suit = Spades | Hearts | Diamonds | Clubs

instance Eq Suit where
Spades == Spades = True
Hearts == Hearts = True
Diamonds == Diamonds = True
Clubs == Clubs = True

== _ = False // any other combination
```

#### Boring to write ...

# Defining Eq for Suit

#### Manual definition

```
data Suit = Spades | Hearts | Diamonds | Clubs

instance Eq Suit where
Spades == Spades = True
Hearts == Hearts = True
Diamonds == Diamonds = True
Clubs == Clubs = True
== = = False // any other combination
```

## Boring to write . . .

### Automatic derivation of Eq instance

```
data Suit = Spades | Hearts | Diamonds | Clubs deriving (Eq)
```

## Plan

- Introduction
- 2 Types
- Pattern Matching on Lists
- Input and Output
- 6 Algebraic Datatypes
- Type classes
- Search trees and expression trees
- 8 Monads

### Search trees

#### Definition

A search tree is a binary tree such that at each node Node I  $\times$  r the element  $\times$  is greater than every element in the left subtree I and  $\times$  is less than every element in the right subtree r.

#### Insert value into a search tree

```
insert :: Ord a => a -> BTree a
insert x Leaf = Node Leaf x Leaf
insert x node@(Node I y r)
| x < y = Node (insert x I) y r
| x > y = Node I y (insert x r)
| otherwise = node
```

• Ord a =>... means that the type a must admit comparison

## Expression trees

#### **Definition**

Arithmetic expressions comprising constants and binary operators

```
data Term = Con Integer
| Bin Term Op Term

data Op = Add | Sub | Mul | Div
```

## Expression trees

#### Definition

Arithmetic expressions comprising constants and binary operators

```
data Term = Con Integer
| Bin Term Op Term

data Op = Add | Sub | Mul | Div
```

## Interpretation

```
eval :: Term -> Integer
eval (Con n) = n
eval (Bin t op u) = sys op (eval t) (eval u)

sys Add = (+)
sys Sub = (-)
sys Mul = (*)
sys Div = div
```

## Extending the interpreter

#### Possible extensions

- Error handling
- Counting evaluation steps
- Variables, state
- Output

... but without changing the structure of the interpreter!

## Extending the interpreter

#### Possible extensions

- Error handling
- Counting evaluation steps
- Variables, state
- Output

... but without changing the structure of the interpreter!

#### Monads to the rescue

In each case, we can phrase the extension as a type of commands, as we've seen in the case of I/O.

# Commands for error handling

### Interface: three operations

- raise an error message
- combine computations with error handling (standard bind operation)
- return a value without an error (standard return operation)

# Commands for error handling

### Interface: three operations

- raise an error message
- combine computations with error handling (standard bind operation)
- return a value without an error (standard return operation)

## Datatype for error handling

```
\begin{array}{c} \text{data Exception a} = \text{Raise String} \\ & | \text{Return a} \end{array}
```

- errors are represented by strings
- a is the type of returned values

#### The Monad Interface

## The type class Monad

```
class Monad m where
(>>=) :: m a -> (a -> m b) -> m b
return :: a -> m a
fail :: String -> m a
```

Here,  ${\tt m}$  is a type variable that can stand for IO, [], and other **type** constructors.

## Monadic interpretation

## Error handling as a monad

```
instance Monad Exception where

return a = Return a

m >>= f = case m of

Raise s -> Raise s

Return v -> f v

fail s = Raise s
```

# Monadic interpretation

### Error handling as a monad

```
instance Monad Exception where

return a = Return a

m >>= f = case m of

Raise s -> Raise s

Return v -> f v

fail s = Raise s
```

### Monadic interpretation

```
eval :: Term \rightarrow Exception Integer
eval (Con n) = return n
eval (Bin t op u) = eval t >= \ v ->
eval u >= \ w ->
if (op == Div && w == 0)
then fail "div by zero"
else return (sys op v w)
```

# Why would you write an interpreter in this style?

- Easy modification to support other effects / monads.
- It's possible to combine monads modularly to support combinations of effects.

## A monad for counting

The state monad

```
State
```

```
data ST s a = ST (s \rightarrow (a, s))
 _{2} exST (ST sas) = sas
 4 instance Monad (ST s) where
     return a = ST (\slash s -> (a, s))
     m >>= f = ST (\s -> let (a, s') = exST m s in
                            exST (f a) s')
9 type Count a = ST Integer a
incr :: Count ()
| \text{incr} = \text{ST} ((i -> ((), i + 1))
```

## Monadic interpreter with reduction count

Implementation

```
Evaluation

eval :: Term -> Count Integer
eval (Con n) = return n
eval (Bin t op u) = eval t >>= \v ->
eval u >>= \w ->
incr >>
return (sys op v w)
```

## Typical monads

### Already used

- Identity monad
- Exception monad
- State monad
- I/O monad

#### **Others**

- Writer monad: supports a write operation
- Maybe monad: computation that may or may not return a result
- List monad: Multiple results / nondeterminism, backtracking
